The initial inspiration for using groups to approximate population heterogeneity came from a suggestion by John Engberg. One of the most recent, and perhaps most exciting, extensions of these models has been the combination of GBTMs with propensity score modeling to facilitate causal inference in longitudinal studies where randomization to treatment condition is not possible—as is the case in the majority of criminological studies see Haviland et al. All that is required is a zero-order polynomial Group-Based Modeling of Development by a negative intercept.

In the case of the adolescent-onset group, this probability starts at nearly 1. There is a close analogy to this important point from the standard regression model. For a two-group model, the binary logit function is a natural candidate for modeling group membership probability as a function of x_i . The base model as specified by equations 2.

The importance of accounting for the clustering of data at the scale minimum is 3.
